Author’s contribution
The sole author designed, analyzed and interpreted and prepared the manuscript.

ABSTRACT

Aims: To derive analytic formulas for the overall efficacy of corneal collagen crosslinking (CXL) based on coupled kinetic equations including both non-oxygen-mediated (NOM) and oxygen-mediated (OM) type-II mechanisms.

Study Design: modeling the kinetics of CXL.

Place and Duration of Study: Taipei, Taiwan, between June, 2017 and January 2018.

Methodology: Coupled kinetic equations are derived under the quasi-steady state condition for the 3-pathway mechanisms of CXL. For type-I CXL, the riboflavin triplet state [T3] may interact directly with the stroma collagen substrate [A] under NOM, or with the ground-state oxygen [O2] to form reactive oxygen species [O-] under OM. For type-II process, [T3] interacts with [O2] to form a singlet oxygen [1O2]. Both reactive oxygen species (ROS), [O-] and [1O2], can relax to [O2], or interact with the extracellular matrix (or the stroma substrate [A]) for crosslinking.

Results: In the first 3 to 20 seconds, CXL efficacy is governed by both type-I and –II mechanisms, and after that period type-I, NOM is the predominant contribution, while oxygen for OM only plays a limited and transient role, in contrary to the conventionally believed OM-dominant mechanism. The riboflavin profile has a much slower depletion rate than that of oxygen profile. The ratio between NOM-type-I and OM depends on the relative initial concentration of [A] and [1O2] and their diffusion depths in the stroma. The overall CXL efficacy is proportional to the UV light dose (or fluence), the

1. INTRODUCTION

Photochemical kinetics of corneal collagen crosslinking (CXL) and the biomechanical properties of corneal tissue after CXL have been reported and summarized in a recent book [1]. The safety and efficacy issues of CXL have been reported theoretically [2-14]. The critical parameters influencing the efficacy of CXL include: initial concentration and diffusion depth of riboflavin (RF) (for type-I CXL) and oxygen (for type-II CXL), quantum yield, UV light intensity, dose and irradiation duration. Most of the previous models [2-6] are not accurate due to the oversimplified assumptions of constant RF profiles, or non-depleted RF, or UV light intensity following the simple Beer-Lambert law (BLL).

Standard (Dresden) protocols were revised for faster (accelerated) CXL based on Bunsen-Roscoe law (BRL) having a limited validation of UV maximum intensity [13]. Controversial efficacy issues of Dresden versus accelerated corneal crosslinking (A-CXL) have been discussed recently by Lin [13] and a concentration-controlled method (CCM) to improve the efficacy of A-CXL was also proposed [14].

Schumacher et al. [3] reported the NOM-type-I CXL, in contrast to Kling et al. [5] claiming that oxygen-mediated type-II played the critical role of CXL efficacy. Furthermore, Kamaev et al. [2] claimed that CXL is NOM-type-I dominant, while the OM-type-II only plays a limited and transient role. If Kling et al. were correct, then all the reported results of epi-on CXL would not be possible, since only minimum oxygen supply is available [1].

The photochemical kinetics of type-II process and the role of oxygen was reported previously [10]. This article intends to resolve the non-conclusive issues about the role of oxygen in CXL efficacy which should be governed by both OM and NOM, 3-pathway processes, rather than the conventionally believed type-II only (oxygen-mediated) mechanism [5]. Efficacy formulas will be presented to demonstrate the factors determining the relative contribution of NOM and OM.

The coupling between OM and NOM and their efficacy will be analyzed by the derived S formulas, which, to my knowledge, are for the first time available in CXL, although similar kinetics were presented for anti-cancer photodynamic process [15,16], which, however, have ignored the NOM type-I mechanism. This study will focus on the analytic formulas and the important features resulted from these S formulas, whereas detailed numerical simulations will be presented elsewhere.

2. MATERIALS AND METHODS

2.1 Photochemical Kinetic (Type-I and –II)

The photochemical kinetics of CXL is shown in Fig. 1 for both type-I and –II. Greater detailed kinetic of type-II only was published in my prior work [10]. This study will present the combined kinetics. Fig. 1 shows the depletion profile of oxygen which defines the contribution of type-I and type-II in different stage. Typical depletion time of oxygen is about 5 to 15 seconds, for light intensity of 30 to 3 mW/cm², per measured data of Kamaev et al. [2], and takes about 10 minutes for the oxygen to be resupplied or replenished to about 1/3 of its initial state.

Both type-I and type-II reactions can occur simultaneously, and the ratio between these processes depends on the type of photosensitizers (PS) used, the concentrations of PS, substrate and oxygen, the kinetic rates involved in the process, and the light intensity, dose, PS depletion rate etc. More details will be shown later.
As shown in Figs. 2 and 3, the CXL process is described as follows. The ground state RF molecules are excited by the UV light to its singlet excited state (S<sub>1</sub>), which could be relaxed to its ground state or to a triplet excited state (T<sub>3</sub>). In type-I process, (T<sub>3</sub>) could interact directly with the stroma collagen substrate [A] for crosslinking, or could interact with the ground state oxygen, [O<sub>2</sub>], to form reactive superoxide anion radicals (O<sup>-</sup>). For type-II process, (T<sub>3</sub>) interacts with [O<sub>2</sub>] to form oxygen singlet [O<sup>2</sup>]. The reactive oxygen radicals (ROS), [O<sup>2</sup>] or [O<sup>-</sup>], could be relaxed to its ground state oxygen [O<sub>2</sub>], or interacts with the stroma substrate [A] to treat corneal ulcers or to form cross linking.

The kinetics shown in Fig.2 includes both oxygen-mediated (OM) related to the reactive oxygen radicals (ROS), [O<sup>2</sup>] or [O<sup>-</sup>]; and non-oxygen-mediated (NOM) term in type-I given by the direct interaction of the triplet (T<sub>3</sub>) with the stroma collagen substrate [A].

The kinetic equations (based on the kinetics of Fig. 3) for the concentration of various components are shown by using short-hand notations: C (z, t) and C*(z, t) for the RF ground and singlet state [S<sub>1</sub>] and [S<sub>1</sub>]*; X (z, t) and X*(z, t) for the ground state [O<sub>2</sub>] and singlet oxygen [O<sup>*</sup>], Y*(z, t) for superoxide anion radicals [O<sup>-</sup>], T (z, t) for the RF triplet state (T<sub>3</sub>), and [A] for the available extracellular matrix substrate; given by [10,17].

\[
\frac{dC(z,t)}{dt} = -k_0C + k_1C^* + K_4T - K_5(C + s) \quad (1.a)
\]

Fig. 1. Schematics of the oxygen profiles during the CXL process; in the transient stage, both type-I and –II coexist until the oxygen is depleted; then type-I dominates before the oxygen is resupplied or replenished [10]

3 – pathway Kinetics of CXL

Fig. 2. The kinetics of CXL, where [S<sub>0</sub>], [S<sub>1</sub>] and [T<sub>3</sub>] are the ground state, singlet excited state, and triplet excited state of RF molecules. Three pathways are shown for both type-I and type-II process. Ground state oxygen may couple to T<sub>3</sub> to form either singlet oxygen [O<sup>*</sup>], or other reactive radicals [O<sup>-</sup>]. In type-I pathway, T<sub>3</sub> can interact directly with the collagen substrate (A); or with the oxygen (O<sub>2</sub>) to generate a superoxide anion (O<sup>-</sup>); in type-II pathway, T<sub>3</sub> interacts with the ground oxygen (O<sub>2</sub>) to form a singlet oxygen (O<sup>*</sup>) [13]
Fig. 3. The kinetics of CXL showing the rate constants associate with Fig. 2 [10,17]

\[
\begin{align*}
\frac{dC(x,t)}{dt} &= k_0 C - k_3 C^* - k_2 C^* \quad (1.b) \\
\frac{dT(x,t)}{dt} &= k_2 C^* - k_3 T \quad (1.c) \\
\frac{dX(x,t)}{dt} &= s_2 k_3 XT - k_2 X^* \quad (1.d) \\
\frac{dY(x,t)}{dt} &= s_1 k_3 XT - k_4 X^* \quad (1.e) \\
\frac{d[A]}{dt} &= -(k_7 X^* + k_7 Y^* + k_8 [T])[A] \quad (1.g)
\end{align*}
\]

where, \( K_1 = (k_5+k_3 X) \); \( K_2 = [k_2 X^*+k_3 Y^*] \), which includes both OM terms for type-II (\( k_2 X^* \)) and type-I (\( k_3 Y^* \)); \( K_3 = (k_6 X^*+k_7 [A]) \); and \( K_4 = k_4 + k_{12}(C+s) + k_{12} [A] \); \( K_5 = k_{11}(C+s)+k_{11} [A] \); and \( s \) is a low concentration correction related to the diffusion of singlet oxygen [17]. Where \( k_{12} C \) can be neglected, when \( k_{12} C \ll k_5 \) or \( k_{12} [A] \), to avoid the C dependence of \( K_1 \) or \( K_2 \), when deriving the analytic formulas.

In Eq. (1.f), \( s_2 \) and \( s_1 \) are the fraction of triplet-state and oxygen reactions to produce \(^1\)O\(_2\) (in type-II) and other ROS (in Type I) reactions. Eq. (1.f) includes an oxygen source term given by \( P=-(1-X/X_0) P_0 \), with a maximum rate constant \( P_0 \), where \( (1-X/X_0) \) is included to avoid the negative value of oxygen. We note, in Eq. (1.a), that \(-k_0 C\) and \(-k_3 C^*\) are related to the RF depletion, whereas \(+k_4 C^*\) and \(k_7 T\) are the regeneration of RF (due to the reaction of [T] and oxygen). Therefore, the presence of oxygen will reduce the RF depletion due to the NOM-type-I mechanism. However, the conventionally belief, that there is no RF depletion in type-II pathway is not correct, because RF is depleted to produce triplet state given by its quantum yield, \( q=k_4/(k_1+k_2) \), in both type-I and type-II. More details will be shown later.

Compared to our previous type-II only model [10], we have added new terms in Eq. (1.a): the type-I NOM term, \( k_5 [A] \), and the OM term, \( k_{12} [A] + k_{11} Y^* \), due to other radicals, \([O\cdot]\). Eq. (1.f) also includes extra NOM and OM terms, \( k_{12} [A] + k_{11} Y^* \).

The dynamic UV light intensity is given by

\[
\frac{dC(x,t)}{dx} = -A'(z,t)I(z,t) \quad (2.a)
\]

\[
A'(z,t) = 2.3 [(a'-b')C + b' F' + Q] \quad (2.b)
\]

where \( F'(z)=1-0.25z/D \), with \( D \) being the initial diffusion depth of RF; and \( a'=83.6 \lambda , \lambda \) being the UV light wavelength; \( a'=204 (1/%/cm) \) and \( b' \) are the extinction coefficients of RF and the photolysis product, respectively; \( Q=13.9 (1/cm) \) is the absorption coefficient of the stroma at the UV wavelength.

We note that Eq. (1) was also presented by Kim et al. [16], however, they have assumed a constant UV intensity, i.e., Eq. (2) are not proposed. They also ignored the contribution
from the type-I term, \(k_s[A]\), since type-II is dominant in their anti-cancer process. Most of the previous model have also ignored the dynamic of UV intensity given by Eq. (2) and the depth-dependent profile of RF and UV intensity [2-6]. Accurate solutions of Eq. (1) and (2) require numerical simulations. For analytic formulas, I will use an effective \(A(z,t)\) or its mean value, such that \(A'(z,t)\) becomes time-independent in solving Eq. (1).

Eq. (1.f) includes both OM and NOM. Eq. (1.c) includes one extra term, \(k_d[A]\), for the reduction of the triplet RF due to its direct coupling to the collagen substrate \([A]\), when type-I process occurs simultaneously with type-II. This extra RF depletion term was ignored in previous modeling [2-6]. In Eq. (5.d) for the oxygen concentration, we have included a source term \((P)\) to count for the situation when there is an external continuing supply, or nature replenishment, besides the initial oxygen in the stroma, which will be defined by an oxygen diffusion function later. In general, \(P\) is time-dependent and can be positive or negative [15].

The kinetic equations (1) and (2) may be numerically calculated to find the CXL efficacy, which however is too complex for us to analyze the roles of each of the parameters. For comprehensive modeling we will use the so-called quasi-steady state assumption [15] described as follows. The life time of the singlet and triplet states of photosensitizer \((C^*\) and \(T)\) and the singlet oxygen \((X^*)\) are very short (ns to \(\mu s\) time scale) since they either decay or react with cellular matrix immediately after they are created. Thus, one may set the time dependences, \(dC^*/dt=dt=dX^*/dt=0\), or the quasi-steady-state state. We first find the steady-state solutions: \(T= aqIG/k_5\), \(X^*= s_2(aqIG)/K_2; Y^*= s_1(aqIG)/K_1\), which in turn gives

\[
\frac{dC(t)}{dt} = -(aqI)[g + K_{12} G]C \tag{3.a}
\]

\[
\frac{d[G(t)]}{dt} = -(NaqI)[s_1 + s_2]G + P \tag{3.b}
\]

\[
G(t) = C[O_2]/([O_2] + k) \tag{3.c}
\]

\[
g(t) = (k_9/k_3)[A]/([O_2] + k) \tag{3.d}
\]

where \(q\) is the triplet state \([T]\) quantum yield given by \(q=k_y/(k_1+k_2)\); \(K_{12} = (s_1k_{11}+s_2k_{12}/k_2)\); \(K_1 = k_{11}(C+s)k_{T1}[A]\); \(K_2 = k_6 + k_{12}(C+s)+k_{T2}[A]\); \(k = k_5/k_3 + (k_9/k_3)[A]\).

In Eq. (3.b), we added a new parameter \((N)\) to fit the measured data of oxygen time-profile (to be discussed later).

The above coupled equations will be solved under an initial conditions having initial profiles defined by their diffusion depths, \(D\) (for RF), \(D'/\) (for oxygen), and \(2D\) (for UV intensity, given by \(C_0(z)=1-0.5z/D\), \([O_2](z)=1-0.5z/D\), and \(I_0(z)=1-0.5z/2D\), respectively).

### 2.2 The S Formulas for Overall Efficacy

The normalized efficacy defined by \(C_{eff} = 1-A/[A]/[A]_0 = \exp(-S)\), with \(S\)-function for type-I (\(S_I\)) and type-II (\(S_2\)) defined by Eq. (1.f) and can be further derived as follows. The type-I efficacy defined by Eq. (1.f) may be further expressed by rate equation of conversion of collagen monomers \([M]\) to polymers, where the NOM term of Eq. (1.a), \(g = k_8[A]/([O_2]+k)\), in Eq. (3.d) and (1.f), is replaced by an overall rate constant \((K)\) including all polymerization chain reactions. The more accurate \(S_I\) is given by [11].

\[
S_1 = \int_0^1 \left( [A] \sqrt{aK'[Cl]} + f k_T [A] Y^* \right) \, dt \tag{4.a}
\]

where \(K'\) is an overall rate constant (excluding the \(k_{T1}\) pathway) for the NOM reactions; and the ROS-mediated term is given by the second term, \(k_T Y^* [A]\), \(Y^*\) being the singlet oxygen concentration, which was ignored in our previous CXL type-I modeling [11].

Similarly, the \(S_2\)-function for type-II \((S_2)\) is given by, from Eq. (1.f),

\[
S_2 = \int_0^1 (f k_T [A] X^*) \, dt \tag{4.b}
\]

Using the steady-state value of \([T], [X^*]\) and \([Y^*]\), the associate \(S\)-functions for the efficacy for type-I and type-II are given by, from Eq. (4),

\[
S_1 = \int_0^1 ([A] \sqrt{aK'[Cl(z,t)]} + (s_1aK_q)(z,t)G) \, dt \tag{5.a}
\]

\[
S_2 = (s_2aq) \int_0^1 (K I(z,t)G) \, dt \tag{5.b}
\]

where \(K = 0.65[A]/(1+C+0.65 [A])\), in which we have used the values [2]: \(k_{T2}=k_{T1}=1.7x10^5 \) (1/s), \(k_6=k_{T1}=2.6x10^5 \) (1/s) and \(k_{T2}/k_6=0.65\).

The first term in Eq. (5.a) relates with the direct coupling of triplet state \([T]\) with the substrate \([A]\) under hypoxic conditions or any other NOM
reactions; and the second term relates with the (ROS)-mediated reactions (in type-I). f is the fraction of all ROS (including singlet oxygen) interacting with acceptors [A], or the oxygen-mediated (NOM) reactions in type-I and type-II. $s_2$ and $s_3$ are the fraction of [O$_2$] interacting with [T] to produce singlet oxygen (in type-II) and other ROS (in type-I), respectively; with typical values of (for RF) $s_1=0.01$ and $s_2=0.49$; or singlet oxygen is the dominant ROS. In comparison, for rose Bengal, $s_1=0.2$ and $s_2=0.8$ [17].

The ratio between OM and NOM-term. Type-I is given first term of Eq. (5.a), $R=K_{12}/g$, with $K_{12}=s_2/(1+(C+s)+0.65[A])$. For typical values of $k_s/k_3=0.05$, $k_7/k_2=3$, and initial value $C_0=0.1$, $[O_2]=7.3$, $R=0.15/(0.05[A]=3/[A]$. Therefore, $R=3$, when $[A]=1$; $R=0.3$, when $[A]=10$.

For the situation that $R<<1$ (or $K_{12}<g$, with $[A]>10$), the major depletion of C(z,t) is caused by the NOM term. Type-II OM dominant process claimed by Kling et al. [8] is valid only for the special case that $[A]<1$, or $R>>1$, such as rose Bengal CXL in green light. However, in RF-CXL, type-I should be dominant. Typical values of above rate constants depend on the properties of the photosensitizers. For ALA and Photofrin used in anti-cancer reported by Zhu et al. [6] $s_1=0.2$, $s_2=0.8$; and $s_3=0.01$, $s_4=0.49$ for riboflavin CXL.

The initial concentration profiles (at t=0) of the RF and oxygen may be calculated or measured based on Fick’s second law of diffusion [9,10,14]. For analytic solution, we will chose the distribution profile given by [3,6]: $F(z,D) = 1 - 0.5z/D$ for RF solution, or $C(z,t)=C_0F(z)$, with a diffusion depth $D$ in the stroma; and $F(D',z) = 1 - 0.5z/D'$ for the oxygen initial concentration, or $X(z,0)=X_0F(D',z)$, with a different diffusion depth $D'$. The typical diffusion depths are: $D = 200$ to $500$ um and $D' = 100$ to $200$ um.

The prior work of Zhu and Kim et al. [16,17], Schumacher et al. [3], and Kling [5] assumed a constant UV light intensity and ignored the RF depletion, i.e., $X(z,t)=X_0$, which is a constant in Eq. (2.b), based on the conventional Beer-Lambert law which overestimated the A(z,t) as its initial value when $t=0$. The prior work also assumes a flat RF concentration, or $F(z,t)=1$ and used an oversimplified model to assume no absorption of the photolytic products, or $b'=0$. The extra RF depletion term ($g$) due to direct coupling of [T] and [A], in Eq. (3.a), was ignored in previous model work [2-6,16]. Therefore, our modeling system based on Eq. (3) and (5) is much more accurate than the prior works in describing the CXL process when type-I and type-II coexist, specially for the initial stage prior to the oxygen depletion, and after the transient state with type-I dominant.

According to the proposed mechanism of Kamaev et al. [2], under aerobic conditions, they believe that CXL in the cornea is initiated due to the direct interaction between the substrate and excited RF triplets, with singlet oxygen playing a limited and transient role in the process. In contrary, Kling et al. [3] believed that type-II is the predominant mechanism. Our new modeling system demonstrated theoretically that CXL using RF as the PS is predominated by the NOM term of type-I, or the direct coupling of triplet RF to the substrate [A], since the OM pathways (in both type-I and II) via singlet oxygen play a limited and transient role in the process per Kamaev et al. [2], who proposed the mechanisms but did not develop the detailed macroscopic equations shown in this study.

3.2 Analytic Formulas

We will first derive the analytic formulas for the efficacy of type-I and -II CXL as follows.
depletion time of oxygen is about 3 to 20 seconds, for light intensity of 30 to 3 mW/cm², per measured data of Kamaev et al. [2], and takes about 10 minutes for the oxygen to recover to 1/3 of its initial state.

For the situation that R<<1 (or K₁₁₂G<<g, with |A|>10), the major depletion of C(z,t) is caused by the NOM term. Solving for Eq. (3.a) to obtain an approximated C(z,t)= C₀Fexp(-Bt), with B =aqgI(z), with I(z) given by Eq. (2) and A' given by its mean value or steady-state fit-value such that it becomes time-independent [9,11]. Using this C(z,t) we may solve for [O₂] in Eq. (3.b). We note that the depletion time (t₀) of oxygen is about 5 to 20 seconds, which is much shorter than 1/b, to be shown later.

For the other situation that R>>1 (or K₁₁₂G>>g, with |A|<0.5), the major depletion of C(z,t) is caused by the OM term. Solving for dC/dt= -bG, with b=0.3E₀=0.31, I(z) in mW/cm², and rotated for [O₂] vs. t, which also give the depletion time of oxygen is about 3 to 20 seconds, which is much shorter than 1/b, to be shown later.

Case (1) and for g<<K₁₁₂G, without oxygen source term (or for the transient stage), P=0, analytic solution is given by the solution of the nonlinear equation of the UV light exposure time (t₀)

\[ Y_2-Y_1=0.5N(b/B)C_0F[1-exp(-Bt)] \]

\[ t=(1/b)ln[Y_2-Y_1-k] \]  

with \( Y_2=[O₂]_F+kln[O₂] \), \( Y_1=[O₂]_F+kln([O₂]_F) \); B=b(g+K₁₁₂), is the effective rate constant for RF depletion. \([O₂]_F \) is the oxygen initial concentration. Given Eq. (6.b), we may plot the curve for t vs. \([O₂] \), and rotated for \([O₂] \) vs. t, which also give the profile for C(z,t) vs. t, and integration of K(z)C(z,t)G(z,t), \( s_1(z)G(z,t) \) and \( s_2(z)G(z,t) \) give us the \( S_1 \) and \( S_2 \) function defined by Eq. (5).

Case (2). For P>0, and for g<<K₁₁₂G, I also obtained the approximated solution for oxygen

\[ [O₂]_F = [O₂]_F - Nln[1 + b \cdot t] + N_2P_0t \]  

where \( b'=K_{12}b \), with \( K_{12}=(s_1+s_2)(C_0F)/[1+0.65[\text{A}]] \), for (C+s)<<1, and \( k_1=k_0=0.65; b'=aqgI(z), \) with \( a=0.31, \) \( I(z) \) in mW/cm²; \( P=(1-[O₂]/[O₂])P_0; F(z,D) = 1 - 0.5z/D' \) and \( D' \) and \( D \) are the initial diffusion depth of oxygen and RF, respectively. Eq. (7) shows that \([O₂]_F \) is a decreasing function of z and UV intensity, since \( b=aqgI(z) \). N and \( N' \) are fit parameters to be found numerically. In Eq. (6) and (7), parameter N is fit to the measured data of Kamaev et al. [2]. From Eq. (7), for \( b=0.3E_0=0.31t \) at \( z=0, F'=1, C_0=0.1, K_{112}=0.5C_0, N=[O₂]/ln(1+0.15C_0E_0) \). Therefore, \( N=(14,11.4, 9.2, 8.6) \) for dose \( E_0 = (45, 60, 80, 90) \) mJ/cm², when \([O₂]_F \) is completely depleted, where \( E_0=60 \) mJ/cm² represents \([t=70] \) for \( I_0=3 \) mW/cm², or \([t=7 \text{ s for } I_0=30 \text{ mW/cm}^2] \) etc.

Using C(z,t)=C₀F[(1+(K₁₁₂G)bt)] and time integral of bG, with G approximated by C(z,t) in Eq. (5.b), I obtain the analytic formula for the S-function for the case of g<<K₁₁₂G and P=0.

The efficacy of NOM-type-I (S₁) and OM-type-II (S₂) can be calculated by the time integral of \([A]\sqrt{I(z)}C(z,t) \) and \([A]I(z)[C(z,t)]_F \) as shown by Eq. (5), respectively, given by [10,11]:

\[ S_1 = E'[A]/[4K'C_0F(z)exp(Az)/[aqgI_0]] \]  

with \( E'(z,t) = [1-exp(-0.5bt)] \), for the case that g<<K₁₁₂G and after oxygen is depleted. K' is an effective rate constant for polymerization [11]. Eq. (8.b) shows that S is a decreasing function of I₀, but increasing function of z (for steady-state). We note that Eq. (8.a) is available only for the case that \( g=1 \), or when oxygen is depleted such that \([O₂]_F \) in g-function can be neglected; otherwise, numerical simulation is needed. For transient state, S₁ has optimal depth (z*) which is proportional to \( \ln(aqI_0)/A \).

Using Eq. (7) and the approximated C(z,t), I also obtained the approximated function from Eq. (5.b) (for \( f=0.5 \)),

\[ S_2 = 0.32[A](H ln(1 + b't) + H'P_0t^2) \]  

where \( b'=K_{112}b \), with \( b=agI(z), \) \( H=[(O₂F)'/((O₂F)^2)] \), \( H'=N_2(1-0.67b't) \), with \( N_2=0.5(1 + k_0[A]/k_0)C_0F(NP_0-0.5Nb_0C_0F)/(F[O₂])^2; [O₂]_F \) is the initial oxygen concentration.

Eq. (8.b) shows that S₂ is a decreasing function of z, since \( b=agI(z) \). We note that for the case of \( P_0=0, \) S₂ depends only on the UV light dose, i.e., it has the same steady-state for the same dose. However, for \( P_0>0, \) S₂ is higher for lower intensity (with the same dose) to be shown later.

The above S formulas show that NOM-type-I efficacy (S₁) is proportional to the initial RF
concentration \([A](C_0F)/(aql_0)\), with no contribution from oxygen \([O_2]\), except a small term in \(g\) of Eq.(3.d); whereas \(S_2\) is proportional to both \([A]C_0(z,t)\) and the initial oxygen concentration, \([O_3]\). Therefore, resupply of RF solution, under a so-called controlled-concentration-method (CCM) during the UV exposure will increase significantly the overall efficacy, specially for accelerated CXL which has lower efficacy than the standard Dresden low-power (under non-controlled concentration) [13].

Similarly, for the second term of Eq. (5.a) for OM-type-I efficacy is given by, \(S_2=(s_1/s_2)S_2\). Typical values are: \(f=0.5\) and \(s_1=0.01\), and \(s_2=0.49\) (for riboflavin).

Knowing the \(S\) functions of type-I and type-II, the normalized overall CXL efficacy is given by \(C_{eff}=0.5[CX_1 + CX_2]\), with \(CX_1=1-\exp(-S_1)\), \(CX_2=1-\exp(-S_2)\), which is better than our previous formula [10] \(C_{eff}=1-\exp(-[S_1+S_2])\), because \(S_1\) and \(S_2\) have different basis in normalization, based on available monomers (in NOM-type-I) and substrate (in OM-type-II), in addition to deferent rate constants.

### 3.3 Dynamic Profiles

Fig. 4 shows the numerical results of Eq. (3) for oxygen and RF concentration profiles for intensity \(I_0=(3.9,18)\) mW/cm\(^2\) and \(z=0\); using a fit \(N=10\), for depletion time \(t_0=(20,7.2)\) s for \(I_0=(3.9,18)\) mW/cm\(^2\), for \(C_0=0.1, f=q=0.5, a=0.62\). The fit-N is used to achieve oxygen profiles matching the similar trends of the measured data of Kamaev [2]. Other input parameters are used [2,4]: \([O_2]=7.3, k_0/k_1=1, k_0/k_3=0.05, [A]=1.0, K=(s_1+s_2)/(1+C+0.65[A]), k_{72}=k_{71}=1.7*10^{-8} \,(1/s), k_0=k_{11}=k_{12}=2.6*10^{-10} \,(1/s), D=500\,um, D'=200\,um, s_1=0.01, s_2=0.49, and P_0=0.05. Fig. 4 also shows that RF depletion is about 5 times slower than oxygen.

Fig. 4 shows that RF concentration, \(C(z,t)\), has a much slower decaying rate (about 5 times) than oxygen profiles. This can be easily realized by the RF effective rate \(K_{12}(C_0F)^2b\) which is much smaller than the decaying rate of oxygen, \(NbK_{12}C_0F\) (with \(N=10\)).

![Fig. 4. The dynamic profiles of ground state oxygen (solid curves) and riboflavin (dashed curves) concentration (on surface, \(z=0\)), for intensity \(I_0=(3.9,18)\) mW/cm\(^2\) (for curves in red, green, blue), for \(C_0=0.1\%, [O_2]=7.3\,mg/L, D=500\,um, D'=200\,um, and oxygen supply rate \(P_0=0.05\) (1/s)](image)

Fig. 5 shows the type-II efficacy \((S_2)\) for intensity \(I_0=(3.9,18)\) mW/cm\(^2\). If no oxygen supply (or \(P_0=0\)), higher intensity has a faster rising curve, but all intensities have the same steady state value (as shown by the left figure). However, for \(P_0>0\), high intensity has lower steady state value due to the faster oxygen depletion-profiles shown in Fig. 4. In comparison, Fig. 6 shows the \(S\)-function profiles for NOM-type-I\((S_1)\), the first term of Eq. (5.a), for intensity \(I_0=(3.9,18,30)\) mW/cm\(^2\), based on analytic formula, Eq. (8.a) [9,11].

![Fig. 5. The S-function profiles for Type-II \((S_2)\) associate to Fig. 4, but for \(P_0=0\) (left figure) and \(P_0=0.05\) (right figure)](image)
Eq. (8) and (9) show that NOM-type-I efficacy \((S)\) is proportional to \([A]([C_2F]/[aq])\), but not oxygen \([O_2]\), whereas OM-type-II efficacy \((S_2)\) depends on both \(C(z, t)\) and \([O_2]\). Moreover, both \(S_1\) and \(S_2\) have similar trend that lower steady state efficacy in higher intensity. However, they have opposite trends on their z-dependence, where NOM-type-I (type-II) is an increasing (decreasing) function of \(z\) [9-11], for the anterior range of \(z<400\) um.

### 3.4 Summary of Important CXL Features

From the analytic formulas Eq. (5) to Eq. (8) and the calculated data shown in Figs. 4 to 6, the key features of type-I and type-II CXL are summarized and compared as follows:

(a) Oxygen is required for ROS-mediated type-I and type-II CXL, but it is not required in NOM-mediated type-I. The ratio in RF depletion and efficacy due to OM and NOM-type-I is defined by \(R=3/[A]\). Therefore, for large substrate concentration (with \([A]>10\) mg/L), type-I is dominant; whereas when \([A]<1\) mg/L, type-II-OM is dominant but only plays a limited and transient state role for \(t<t_0\), with \(t_0\) being the depletion time of oxygen.

(b) As shown by Fig. 4, in the transient stage (about 3 to 20 seconds), both type-I and type-II coexist until the oxygen is depleted; then type-I dominates before the oxygen is resupplied or replenished. Fig. 4 also shows that RF depletion is about 5 times slower than that of oxygen (Fig. 4). Therefore, at the time oxygen is depleted, (or OM-type-II reaches its steady-state efficacy), approximately 40% of RF is still available to achieve NOM-type-I process.

(c) Both type-I and type-II efficacy are nonlinear increasing function of the UV light dose (or fluence) in the transient state. but they have different functional forms given by Eq. (5). Type-II and OM-type-I efficacy have similar functional form and are proportional to \(b\), or the UV light dose \((I(t))\); whereas the NOM-type-I is proportional to \(I^0.5\), or \(I^0.5\) (for a given dose) [9, 11].

(d) Both NOM-type-I and type-II shows the similar trend that higher intensity has lower steady-state efficacy, as shown by Fig. 5 and 6.

(e) NOM-type-I has a steady-state efficacy increasing to the depth \((z)\), whereas type-II and OM-type-I has opposite trend, decreasing function of \(z\).

(f) Larger diffusion depths (D or \(D')\) achieve higher efficacy in both type-I and II, as shown by the diffusion equations, \(F=1-0.5z/D\) and \(F'=1-0.5z/D'\).

(g) In type-II CXL, in the absence of oxygen supply (or \(P_2=0\)), higher intensity has a faster rising curve, but all intensities reach the same steady state value (as shown by the left figure of fig.5). However, for \(P_2>0\), high intensity has lower steady state value due to the faster oxygen depletion-profiles shown in Fig. 4.

(h) RF depletion in type-I is partially compensated by the RF regeneration in the presence of oxygen given by the \(g\) factor in Eq. (3.a) which is a decreasing function of oxygen.

(i) The overall CXL efficacy, given by CX1+ CXL2, is governed by the time integration of \(I(z)C(z, t)\) and \(I(z)C(z, t)[O_2]\), for type-I and type-II, respectively. When either \(C(z, t)\) or \([O_2]\) is largely depleted, the CXL efficacy reaches its saturation level, which can not be improved by applying a higher dose (or longer exposure time), unless there are resupply of \(C(z, t)\) and/or \([O_2]\) during the UV exposure. A so-called RF concentration-controlled method (CCM) was proposed for type-I [13]. Similarly, one may improve the type-II efficacy by external supply of high-pressure-oxygen, rather than its natural diffusion from air.

This study focuses on the derivation of analytic formulas and predicted features derived from them, whereas greater details of the roles of each of the components on the overall CXL...
efficacy will be shown elsewhere by numerical solution of Eq. (5), including diffusion depth (D, D’), quantum yield (q), RF depletion rate (aqgl), oxygen depletion rate (Nb), and the oxygen source term (P0). The formulas developed in this study provide guidance for further clinical studies. The features predicted in this study are based on a modeling system which may not represent a real CXL system. Moreover, parameters (or the rate constants k_i) used in the calculations would require further clinical measurement for more accurate values. Greater details on the debating issues and a critical review on the kinetic and efficacy and optimal protocols of CXL will be published elsewhere.

4. CONCLUSION

In the transient state (3 to 20 seconds), CXL efficacy is governed by both type-I and –II mechanisms, and after that period the NOM-type-I is dominant, while oxygen for OM-process only plays a limited and transient role, in contrary to the conventional belief that OM-dominant mechanism. A new protocol using CCM can improve the efficacy in accelerated CX, which is less efficient than the Dresden (low intensity) CXL under the normal, non-controlled methods.
